- **eval function -**
  - used to evaluate expression
  - it always works on string only

e.g. - Syntax - a = eval(expression)
expression = " 20+10/3 * 4"

eval(20+2) ✗ eval("20+2") ✓

- as per need result's data type also change.
- if eval has str input it gives error. cause it can't convert str into str. so give it " " extra.

- **input function -**
  - it is used to accept data from ~~users~~, console / Terminal
  - user ? : use the s/w
  - programmer ? : creates the s/w.
  - Syntax - V= input("Msg")

e.g. -
```
s1 = input("First Num: ")   # 7
s2 = input("Sec Num: ")     # 4
sum = s1 + s2               → o/p - 74
per = (sum/20) * 100        → error
```

- it means input() always gives val. in string.

```
∴ s1 = int(s1)      sum = s1 + s2      per = (sum/20) * 100
  s2 = int(s2)      print(sum)         # o/p - 11
                    print(per)         # o/p - ---
```

- Type casting of data is required.

OR.

```
s1 = int(input("First Num"))   # 1
s2 = int(input("Sec Num"))     # 2
sum = s1 + s2
print(sum)   # o/p = 3
```
